Abstract. In this article we explain how perceptual control of synthesis processes can be achieved through a multidisciplinary approach relating physical and signal properties of sound sources to evocations induced by sounds. This approach is applied to environmental and abstract sounds in 3 different experiments. In the first experiment a perceptual control of synthesized impact sounds evoking sound sources of different materials and shapes is presented. The second experiment describes an immersive environmental synthesizer simulating different kinds of environmental sounds evoking natural events such as rain, waves, wind and fire. In the last example motion evoked by abstract sounds is investigated. A tool for describing perceived motion through drawings is proposed in this case.

Keywords: perceptual control, synthesis, analysis, acoustic descriptors, environmental sounds, abstract sounds

1 Introduction

The development and the optimization of synthesis models have been important research issues since computers produced the first sounds in the early sixties [20]. As computers became increasingly powerful, real-time implementation of synthesis became possible and new research fields related to the control and the development of digital musical instruments appeared. One of the main challenges linked to such fields is the mapping between the control parameters of the interface and the synthesis parameters. Certain synthesis algorithms such as additive synthesis [17, 16, 4] allow for a very precise reconstruction of sounds, but contain a large number of parameters (several hundreds in the case of piano synthesis), which makes the mapping between the control device and the synthesis model complicated. Other synthesis approaches such as global or non-linear approaches (e.g. frequency modulation (FM) or waveshaping [9, 7]) are easier to implement and to control since they contain fewer synthesis parameters, but do not allow for a precise resynthesis. This means that the control device cannot be dissociated from the synthesis model when conceiving a digital musical instrument and even more, a genuine musical interface should go past the technical stage to integrate the creative thought [14]. So far, a large number of control

devices have been developed for musical purposes [25], but only a few are being actively used in musical contexts either because the control is not sufficiently well adapted to performance situations or because they do not offer an adequate sound control. This means that the control of digital musical instruments is still an issue that necessitates more investigations. Nowadays, sounds are used in a large number of applications (e.g. car industry, video games, radio, cinema, medicine, tourism, . . .) since new research domains where sounds are investigated to inform or guide persons (e.g. auditory display, sound design, virtual reality, . . .) have developed. Researchers within these domains have traditionally made use of prerecorded sounds, but since important progress has been achieved concerning the development of efficient and realistic synthesis models, an increasing interest for synthesis solutions has lately been observed [8, 29, 33]. The control requirements related to such applications differ from musical control devices since the role of the sounds in this case is to provide specific information to the end users. Hence, a perceptual control that makes it possible to control sounds from semantic labels, gestures or drawings would be of great interest for such applications. Such control implies that perceptual and cognitive aspects are taken into account in order to understand how a sound is perceived and interpreted. Why are we for instance able to recognize the material of falling objects simply from the sounds they produce, or why do we easily accept the ersatz of horse hooves made by the noise produced when somebody is knocking coconuts together? Previous studies [6, 28] have shown that the processing of both linguistic and non-linguistic target sounds in conceptual priming tests elicited similar relationships in the congruity processing. These results indicate that it should be possible to draw up a real *language of sounds*. A certain number of questions have to be answered before such a language can be defined, in particular whether the identification of a sound event through the signal is linked to the presence of specific acoustic morphologies, so-called invariants that can be identified from signal analyses [22]. If so, the identification of signal invariants should make it possible to propose a perceptual control of sound synthesis processes that enables a direct evocative control.

To develop perceptual control strategies of synthesis processes, it is in the first place necessary to understand the perceptual relevance of the sound attributes that characterize the sound category that is investigated. The sound attributes can be of different types and can either be linked to the physical behavior of the source [13], to the signal parameters [18] or to timbre descriptors obtained from perceptual considerations [21]. In this paper we focus on the perceptual control of environmental sounds and evoked motion by describing how such control can be defined from the identification of signal invariants obtained both from the considerations of physical behavior of the sound generating sources and the perceptual impact of the sounds on the listeners. The general approach proposed to obtain perceptual control strategies is shown in Figure 1.

In the first section of this article, we describe how the perceptual control of an impact sound synthesizer enabling the definition of the sound source through verbal labels can be defined. Then a tool for controlling 3D environmental im-
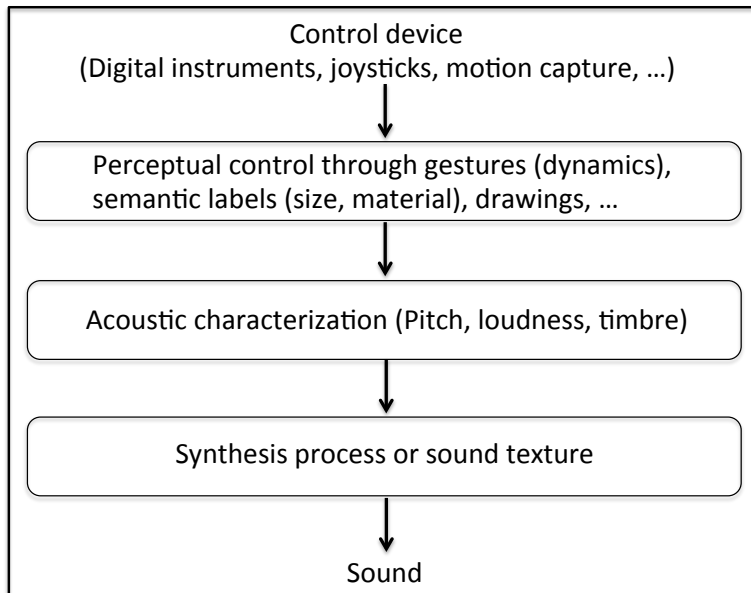

Fig. 1. Synoptics of the perceptual control strategy.

mersive auditory scenes with verbal labels based on a synthesizer adapted to environmental sounds is described. Finally an investigation on perceived motion and how intuitive control parameters for this specific type of evocation can be defined is presented.

2 Impact sound synthesizer

From the physical point of view, impact sounds are typically generated by an object undergoing free oscillations after being excited by an impact, or by a collision with other solid objects. These vibrations are governed by a wave equation and the natural frequencies of the system are obtained from the solution of this equation. These natural frequencies correspond to the frequencies for which the objet is capable of undergoing harmonic motion. The wave propagation depends on the characteristics of the object that influences two physical phenomena, i.e. dispersion (due to the stiffness of the material) and dissipation (due to loss mechanisms). Dispersion results from the fact that the wave propagation speed varies with the frequency and introduces inharmonicity in the spectrum. Dissipation is directly linked to the damping of the sound and is generally frequency-dependent. The perceptual relevance of these phenomena and how they contribute to the identification of impact sounds will be discussed in the next section.

2.1 Invariant sound structures characterizing impact sounds

Impact sounds have been largely investigated in the literature. In particular, some links between the physical characteristics of actions (impact, bouncing . . .) and sound sources (material, shape, size, cavity . . .) and their perceptual correlates were established (see [2, 1] for a review). For instance, the perception of the hardness of a mallet impacting an object is related to the characteristics of the attack time. The perception of material seems to be linked to the characteristics of the damping that is generally frequency-dependent: high frequency components are damped more heavily than low frequency components. In addition to the damping, we concluded that the density of spectral components which is directly linked to the perceived roughness, is also relevant for the distinction between metal versus glass and wood categories [2, 1]. The perceived shape of the object is related to the distribution of the spectral components of the produced sound. It can therefore be assumed that both the inharmonicity and the roughness determine the perceived shape of the object. From a physical point of view, large objects vibrate at lower eigenfrequencies than small ones. Hence, the perceived size of the object is mainly based on the pitch. For complex sounds, the determination of pitch is still an open issue. In some cases, the pitch may not correspond to an actual component of the spectrum and both spectral and virtual pitches are elicited [30]. However, for quasi-harmonic sounds, we assume that the pitch is linked to the fundamental frequency.

These considerations allowed us to identify signal morphologies (i.e. invariants) conveying relevant information on the perceived material, size, shape and type of impact on an object. A mapping strategy defining a link between synthesis parameters, acoustic descriptors and perceptual control parameters can then be defined, as described in the next section.

2.2 Control of the impact sound synthesizer

To develop a perceptual control of impact sounds based on semantic description of the sound source, a mapping strategy between synthesis parameters (low level), acoustic descriptors (middle level) and semantic labels (high level) characterizing the evoked sound object was defined. The mapping strategy that was chosen is based on a three level architecture as seen in Figure 2) [5, 3, 2]. The top layer is composed of verbal descriptions of the object (nature of the material, size and shape, etc.). The middle layer concerns the control of acoustic descriptors that are known to be relevant from the perceptual point of view as described in section 2.1. The bottom layer is dedicated to the control of the parameters of the synthesis model (amplitudes, frequencies and damping coefficients of components). The mapping strategy between verbal descriptions of the sound source and sound descriptors is designed with respect to the previous considerations described in section 2.1. The control of the perceived material is based on the manipulation of damping but also that of spectral sound descriptors such as inharmonicity and roughness. Since the damping is frequency dependent, a damping law was arbitrarily defined and we proposed an exponential function:
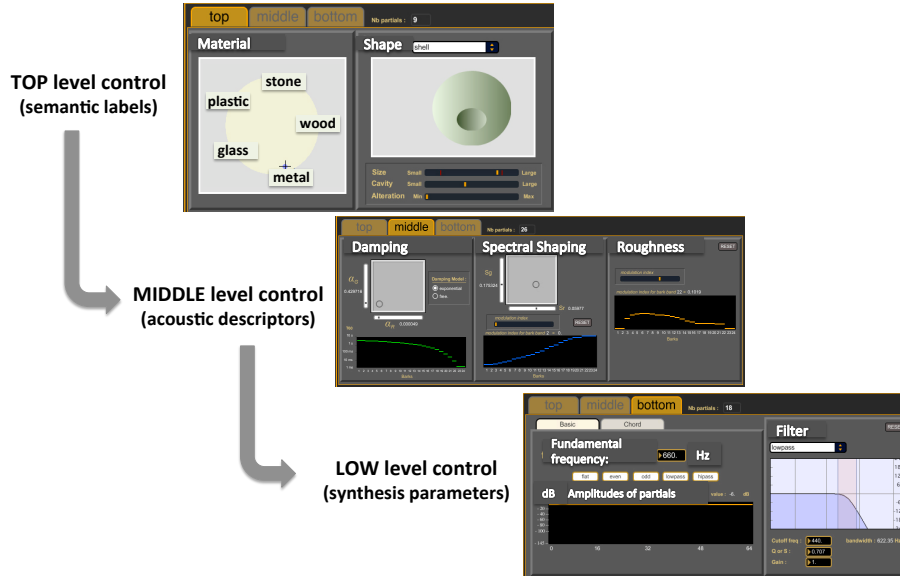

Fig. 2. Three level control strategy of impact sounds

$\alpha(\omega) = e^{(\alpha_G + \alpha_R \omega)}$ characterized by two parameters: a global damping α_G and a relative damping α_R. The choice of an exponential function enables us to reach various damping profiles characteristic of physical materials by acting on a few control parameters. Hence, the control of the damping was effectuated by two parameters. The perception of size is controlled by the frequency of the first component and the perception of shape by the spectral distribution of components defined from inharmonicity and roughness. As for damping, an inharmonicity law characterized by a few parameters was proposed. Some pre-defined presets give direct access to typical inharmonicity profiles, such as those of strings, membranes and plates. The roughness is created by applying amplitude and frequency modulations on the initial sound and can be controlled separately for each Bark band.

The mapping between sound descriptors and synthesis parameters is organized as follows. The damping coefficients of the components are determined from the damping law $\alpha(\omega)$ and their amplitudes from the envelope modulations introduced by the excitation point. The spectral distribution of components (frequency values) are defined from the inharmonicity law and the roughness. A direct control at low level allows for readjustments of this spectral distribution of components by acting separately on the frequency, amplitude and damping coefficients of each component. This mapping between middle and bottom layer

depends on the synthesis model and should be adapted with respect to the chosen synthesis process.

What the control of action is concerned, the hardness of the mallet is controlled by the attack time and the brightness while the perceived force is related to the brightness: the heavier the applied force is, the brighter the sound. The timbre of the generated sound is also strongly influenced by the excitation point of the impact that creates envelope modulations in the spectrum due to the cancellation of modes presenting a node at the point of excitation. From a synthesis point of view, the location of the impact is taken into account by shaping the spectrum with a feed forward comb filter.

3 Immersive environmental sound synthesizer

Impact sounds constitute a specific category of environmental sounds. In this section an immersive synthesizer simulating various kinds of environmental sounds is proposed. These sounds are divided in three main categories according to W. W. Gaver's taxonomy of everyday sound sources: vibrating solids (impact, bouncing, deformation ...) liquid (wave, drop, rain ...) and aerodynamic (wind, fire ...) objects [12, 11]. Based on this taxonomy, we proposed a synthesizer to create and control immersive environmental scenes intended for interactive virtual and augmented reality and sonification applications. Both synthesis and spatialization engines were included in this tool so as to increase the realism and the feeling of being immersed in virtual worlds.

3.1 Invariant sound structures characterizing environmental sounds

In the case of impact sounds, we have seen that physical considerations reveal important properties that can be used to identify the perceived effects of the generated sounds (cf. section 2.1). For other types of environmental sounds such as wave, wind or explosion sounds, the physical considerations involve complex modeling and can less easily be taken into account for synthesis perspective with interactive constraints. Hence the identification of perceptual cues linked to these sound categories was done by the analyses of sound signals representative of these categories. From a perceptual point of view, these sounds evoke a wide range of different physical sources, but interestingly, from a signal point of view, some common acoustic morphologies can be highlighted across these sounds. To date, we concluded on five elementary sound morphologies based on impacts, chirps and noise structures [32]. This finding is based on a heuristic approach that has been verified on a large set of environmental sounds. Actually, granular synthesis processes associated to the morphologies of these five grains have enabled the generation of various environmental sounds such as solid interactions and aerodynamic or liquid sounds. Sounds produced by solid interactions can be characterised from a physical point of view. When a linear approximation applies (small deformation of the structure), the response of a solid object to external forces can be viewed as the convolution of these forces with the modal response

of the object. Such a response is given by a sum of exponentially damped sinusoids, defining the typical "tonal solid grain". Nevertheless, such a type of grain cannot itself account for all kinds of solid impact sounds. Actually, rapidly vanishing impact sounds or sounds characterized by a strong density of modes may rather be modelled as exponentially damped noise. This sound characterization stands for both perceptual and signal points of views, since no obvious pitch can be extracted from such sounds. Exponentially damped noise constitutes the so-called "noisy impact grain". Still dealing with physical considerations, we may design a "liquid grain" that takes into account cavitation phenomena occurring in liquid motion. Cavitation leads to local pressure variations that, from an acoustic point of view, generate time varying frequency components such as exponentially damped linear chirps. Exponentially damped chirps then constitute our third type of grain: the "liquid grain". Aerodynamic sounds generally result from complicated interactions between solids and gases. It is therefore difficult to extract useful information from corresponding physical models. The construction of granular synthesis processes was therefore based on heuristic perceptual expertise defining two kinds of aerodynamic grains: the "whistling grain" consisting in a slowly varying narrow band noise; and the "background aerodynamic grain" consisting in a broadband filtered noise. By combining these five grains using an accurate statistics of appearance, various environmental sounds can be designed such as rainy ambiances, seacoast ambiances, windy environments, fire noises, or solid interactions simulating solid impacts or footstep noises. We currently aim at extracting the parameters corresponding to these grains from the analysis of natural sound, using matching pursuit like methods.

3.2 Control of the environmental sound synthesizer

To develop a perceptual control of the environmental sound synthesizer based on semantic labels, a mapping strategy that enabled the design of complex auditory scenes was defined. In particular, we took into account that some sound sources such as wind or rain are naturally diffuse and wide. Therefore, the control included the location and the spatial extension of sound sources in a 3D space. In contrast with the classical two-stage approach, which consists in first synthesizing a monophonic sound (timbre properties) and then spatializing the sound (spatial position and extension in a 3D space), the architecture of the proposed synthesizer yielded control strategies based on the overall manipulation of timbre and spatial attributes of sound sources at the same level of sound generation [31].

For that purpose, we decided to bring the spatial distribution of the sounds to the lowest level of the sound generation. Indeed, the characterization of each elementary time-localized sound component, that is generally limited to its amplitude, frequency and phase, was augmented by its spatial position in the 3D space. This tremendous addition leads to an increasing number of control possibilities while still being real time compatible thanks to an accurate use of the granular synthesis process in the frequency domain [34]. We then showed that

the control of the spatial distribution of the partials together with the construction of decorrelated versions of the actual sound allowed for the control of the spatial position of the sound source together with the control of its perceived spatial width. These two perceptual spatial dimensions have shown to be of great importance in the design of immersive auditory scenes.

Complex 3D auditory scenes can be intuitively built by combining spatialized sound sources that are themselves built from the elementary "grain" structures (cf. section 3.1).

Fig. 3. Auditory scene of a windy day (wind source surrounding the listener) on a beach (wave coming towards the listener) and including a BBQ sound (fire located at the back right of the listener).

The fire is for instance built from three elementary grains that are a whistling grain (simulating the hissing), a background aerodynamic grain (simulating the background combustion) and noisy impact grains (simulating the cracklings). The grains are generated and launched randomly with respect to time using an accurate statistical law that can be controlled. A global control of the fire intensity, mapped with the control of the grain generation (amplitude and statistical law), can then be designed. The overall control of the environmental scene synthesizer is effectuated through a graphical interface (see figure 3) where the listener is positioned in the center of the scene. Then the user selects the sound sources to be included in the auditory scene among a set of available sources (fire, wind, rain, wave, chimes, footsteps ...) and places them around the lis-

tener by graphically defining the distance and the spatial width of the source. In cases of interactive uses, controls can be achieved using either MIDI interfaces, from data obtained from a graphical engine or other external data sources.

4 Synthesis of evoked motion

A third approach aiming at developing perceptual control devices for synthesized sounds that evoke specific motions is presented in this section. The definition of perceptual control necessitates more thorough investigations in this case than in the two previous cases due to the rather vague notion of perceived motion. Although physics of moving sound sources can to some extent give indications on certain morphologies that characterize specific movements [19], it cannot always explain the notion of perceived motion. In fact, this notion does not only rely on the physical displacement of an object, but can also be linked to temporal evolutions in general or to motion at a more metaphoric level. It is therefore necessary to improve the understanding of perceived dimension of motion linked to the intrinsic properties of sounds. Therefore, an investigation of perceived motion categories obtained through listening tests was effectuated before signal morphologies that characterize the perceptual recognition of motion could be identified.

4.1 Invariant structures of evoked motion

As already mentioned, motion can be directly linked to physical moving sound sources, but can also be considered in more metaphoric ways. Studies on the physical movement of a sound source and the corresponding signal morphologies have been widely described in the literature [10, 27, 26, 35, 19]. One aspect that links physics and perception is the sound pressure that relates the sound intensity to the loudness. The sound pressure is known to vary inversely with the distance between the source and the listener. This rule is highly important from the perceptual point of view [27], and it is possibly decisive in the case of slowly moving sources. It is worth noting that only the relative changes in the sound pressure should be considered in this context. Another important aspect is the timbre and more specifically the brightness variations, which can be physically accounted for in terms of the air absorption [10]. A third phenomenon which is well known in physics is the Doppler effect which explains why frequency shifts can be heard while listening to the siren of an approaching police car [26]. Actually, depending on the relative speed of the source with respect to the listener, the frequency measured at the listener's position varies and the specific time-dependent pattern seems to be a highly relevant cue enabling the listener to construct a mental representation of the trajectory. Finally, the reverberation is another aspect that enables the distinction between close and distant sound sources [15]. A close sound source will produce direct sounds of greater magnitude than the reflected sounds, which means that the reverberation will be weaker for close sound sources than for distant ones.

When considering evoked motion at a more metaphoric level, like for instance in music and cartoon production processes, signal morphologies responsible for the perceived motion cannot be directly linked to physics and must be identified in other ways, for instance through listening tests. The selection of stimuli for such investigations is intricate, since the recognition of the sound producing source might influence the judgement of the perceived motion. For instance, when the sound from a car is presented, the motion that a listener will associate to this sound will most probably be influenced by the possible motions that the car can make, even if the sound might contain other interesting indices that could have evoked motions at more metaphoric levels. To avoid this problem, we therefore decided to investigate motion through a specific sound category, so-called "abstract sounds" which are sounds that cannot be easily associated to an identifiable sound source. Hence, when listeners are asked to describe evocations induced by such sounds, they are forced to concentrate on intrinsic sound properties instead of the sound source. Such sounds, that have been explored by electroacoustic music composers, can be obtained from both recordings (for instance with a microphone close to a sound source) or from synthesized sounds obtained by for instance granular synthesis [23]. In a previous study aiming at investigating semiotics of abstract sounds [28], subjects often referred to various motions when describing these sounds. This observation reinforced our conviction that abstract sounds are well adapted to investigate evoked motion.

As a first approach toward a perceptual control of evoked motion, perceived motion categories were identified through a free categorization test [24]. Subjects were asked to categorize 68 abstract sound and further give a verbal description of each category. Six main categories were identified through this test, i.e. "rotating", "falling down", "approaching", "passing by", "going away", "going up". The extraction of signal features specific to each category revealed a systematic presence of amplitude and frequency modulations in the case of sounds belonging to the category "turning", a logarithmic decrease in amplitude in the category "passing" and amplitude envelopes characteristic of impulsive sounds for the category "falling". Interestingly, several subjects expressed the need to make drawings to describe the perceived motions. This tends to indicate that a relationship between the dynamics of sounds and a graphic representation is intuitive. This observation was decisive for our control strategy investigation presented in the next section.

4.2 Control of evoked motion

In the case of evoked motion the definition of a perceptual control is as previously mentioned less straightforward than in the case of impact sounds and environmental sounds. From the free categorization test described in the previous section, categories of motion were identified along with suitable signal invariants corresponding to each category. However, this test did not directly yield any perceptual cues as to how these evocations might be controlled in a synthesis tool. Therefore, to identify perceptually relevant control parameters corresponding to evoked dynamic patterns, further experiments were conducted in which

subjects were asked to describe the evoked trajectories by drawings. Since hand made drawings would have been difficult to analyze and would have been influenced by differences in people's ability to draw, a parametrized drawing interface was developed, meaning that subjects were given identical drawing tools that required no specific skills. The control parameters available in the interface were based on the findings obtained in the free categorization test, and the accuracy of the drawing was limited to prevent the interface from becoming too complex to handle. The interface is shown in Figure 4.

Fig. 4. Graphical User Interface

Two aspects, i.e. shape and dynamics, enabled the subjects to define the motion. Six parameters were available to draw the shape of the trajectory (shape, size, frequency oscillation, randomness, angle, initial position) and three parameters were available to define the dynamics (initial and final velocity and number of returns). Each time a sound was presented, the subject made a drawing that corresponded to the trajectory he or she had perceived. No time constraint was imposed and the subject could listen to the sound as often as he/she wanted. The dynamics was illustrated by a ball that followed the trajectory while the sound was played.

Results showed that although the subjects used various drawing strategies, equivalent drawings and common parameter values could still be discerned. As far as the shape was concerned, subjects showed good agreement on the distinction between linear and oscillating movements and between wave-like and circular oscillations. This means that these three aspects give a sufficiently exact control of the perceived shape of sound trajectories. As far as the orientation of the trajectory was concerned, only the distinction between horizontal and

vertical seems to be relevant. While there was agreement among subjects about the distinction between the upward/downward direction, the difference between the left/right direction was not relevant. As far as the velocity was concerned, the subjects distinguished between constant and varying velocities, but they did not show good agreement in the way they specified the velocity variations they perceived. This might have been related to the graphical user interface which did not provide a sufficiently precise control of the dynamics according to several subjects.

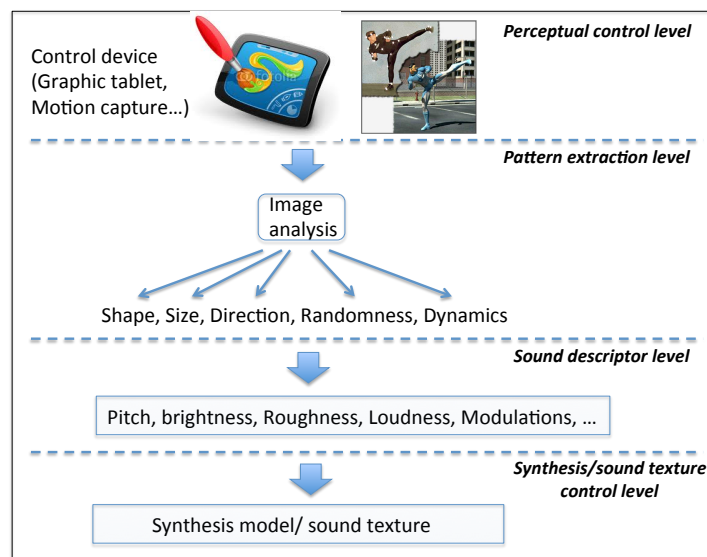

Fig. 5. Generic motion control

The identification of perceptually relevant parameters enabled the definition of a reduced number of control possibilities. Hence 3 kinds of shapes (linear, circular and regular), 3 different directions (south, north and horizontal), and various degrees of oscillation frequencies (high and low), randomness (non, little, much), size (small, medium, large) and dynamics (constant, medium an high speed) were found to be important control parameters that enabled the definition of perceived trajectories. Based on these findings, a generic motion control strategy could hereby be defined as shown in Figure 5. This strategy could be separated in three parts, i.e. a perceptual control level based on drawings, an image processing level dividing the drawings in elementary patterns (i.e. waves, lines, direction, etc) and a third level containing the synthesis algorithm or a sound texture.

5   Conclusion and Discussion

This article describes perceptual control strategies of synthesis processes obtained from the identification of sound structures (invariants) responsible for evocations induced by sounds. In the case of impact sounds, these sound structures are obtained by investigating the perceptual relevance of signal properties related to the physical behavior of the sound sources. Variations of physical phenomena such as dispersion and dissipation make perceptual distinctions possible between different types of objects (i.e. strings versus bars or plates versus membranes) or materials (wood, glass, metal,...). The spectral content of the impact sound, in particular the eigen-frequencies that characterize the modes of a vibrating object, is responsible for the perception of its shape and size. In cases where the physical behavior of sound sources are not known (*e.g.* certain categories of environmental sounds) or cannot explain evocations (*e.g.* metaphoric description of motion), recorded sounds are analyzed and linked to perceptual judgements. Based on the invariant signal structures identified (chirps, noise structures,...), various control strategies that make it possible to intuitively control interacting objects and immersive 3-D environments are developed. With these interfaces, complex 3-D auditory scenes (the sound of rain, waves, wind, fire, etc.) can be intuitively designed. New means of controlling the dynamics of moving sounds via written words or drawings are also proposed.

These developments open the way to new and captivating possibilities for using non-linguistic sounds as a means of communication. Further extending our knowledge in this field will make it possible to develop new tools for generating sound metaphors based on invariant signal structures which can be used to evoke specific mental images via selected perceptual and cognitive attributes. This makes it for instance possible to transform an initially stationary sound into a sound that evokes a motion that follows a specific trajectory.
